Risk sharing and monetary policy transmission

Disclaimer: This paper should not be reported as representing the views of the European Central Bank (ECB). The views expressed are those of the authors and do not necessarily reflect those of the ECB.
Abstract

Using regionally disaggregated data on economic activity, we show that risk sharing plays a key role in shaping the real effects of monetary policy. With weak risk sharing, monetary policy shocks trigger a strong and durable response in output. With strong risk sharing, the response is attenuated, and output reverts to its initial level over the medium term. The attenuating impact of risk sharing via credit and factor markets concentrates over a two-year horizon, whereas fiscal risk sharing operates over longer horizons. Fiscal risk sharing especially benefits poorer regions by shielding them against persistent output contractions after tightening shocks.

Keywords: Monetary Policy; Risk Sharing, Regional Heterogeneity; Local Projections; Quantile Regressions

JEL Classification: C32, E32, E52
Non-technical summary

This paper explores the interaction between monetary policy and risk sharing in a currency union. Exploiting granular data on economic activity for euro area regions, we show that the real effects of monetary policy vary with the strength and composition of risk sharing.

First, the output response to exogenous variation in short-term policy rates is significantly more pronounced and persistent for regions attaining a low degree of risk sharing than for those benefiting from a high degree of risk sharing.

Second, private and public risk-sharing channels act as complements, in that: private channels, operating via credit and factor markets, attenuate the real effects of monetary policy over a horizon of up to two years; public risk sharing, operating via the tax and benefit system, affects monetary policy transmission over longer horizons, just when the private channels lose effectiveness.

Third, public risk-sharing channels prove particularly forceful in shaping the persistence of monetary policy effects in poor regions. With weak fiscal risk sharing, these regions suffer from a durable output contraction in response to a policy rate hike. With strong fiscal risk sharing, poor regions do not only face a weaker output contraction but are also insulated from such hysteresis effects.

These findings offer relevant insights for the debate on the institutional setup of the Economic and Monetary Union (EMU). First, they suggest that heterogeneity in the capacity to absorb shocks via fiscal and market-based channels could contribute to an uneven transmission of monetary policy across jurisdictions. Second, the results point to the benefits of fiscal risk sharing in mitigating the tendency for regional economic divergence to intensify in policy tightening cycles. Third, they indicate that changes to the risk-sharing architecture of an economy may have a major bearing on the aggregate effects of a given change in monetary policy stance.
1 Introduction

The literature on optimal currency areas establishes a clear division of labor in the pursuit of macroeconomic stabilization objectives. Monetary policy is to limit fluctuations in average macroeconomic outcomes by adjusting its union-wide stance in response to symmetric shocks. Risk sharing via public and market-based mechanisms instead should limit the dispersion in macroeconomic outcomes across the currency union by facilitating a geographically differentiated adjustment to asymmetric shocks.

An important, but so far under-explored, aspect in implementing this division of labour is that the impact of these macroeconomic stabilization tools may interact. If a given monetary policy stance exerts a uniform impact on different members of a currency union, its role in limiting average economic fluctuations is unaffected by the role of the risk-sharing architecture in limiting their dispersion. But a growing literature has documented that monetary policy transmits unevenly, for instance due to differences in economic structures, initial conditions, and the institutional landscape of the economy. The resultant heterogeneity in the regional incidence of a uniform monetary policy stance may render its overall impact dependent on the risk-sharing architecture of a currency union. For instance, if risk sharing counteracts the stronger contractionary effects of a monetary policy tightening shock in certain regions, also the average contraction may be attenuated compared to a situation without risk sharing.

The current paper provides empirical evidence on the relevance and nature of the interactions between monetary policy and risk sharing. The analysis exploits region-
ally disaggregated data for the euro area, which exhibit substantial variation in the overall prevalence of risk sharing and in the relative strength of different risk-sharing channels. To estimate the degree and composition of risk sharing, we rely on the well-established framework by Asdrubali et al. (1996). We then feed the resultant coefficients into an empirical macro model, estimated via local projections (Jordà, 2005), to assess how risk sharing, and its breakdown into fiscal and market-based channels, shapes the transmission of monetary policy. Finally, we apply quantile estimation techniques to explore whether the interaction between monetary policy and risk sharing differs across poorer and richer regions.

On this basis, we derive three main insights. First, risk sharing plays a key role in shaping the real effects of monetary policy. For instance, the regional output contraction after a 100 basis point policy rate hike is around 1 percentage point shallower for regions attaining the maximum degree of risk sharing in our sample than for those attaining the minimum degree. Moreover, regions subject to a high degree of risk sharing are less prone to policy-induced hysteresis: while output in regions with minimum risk sharing remains around 1.5 percent below its initial level five years after a monetary policy tightening shock, it fully recovers over this period in regions with maximum risk sharing.

Second, fiscal risk sharing proves particularly forceful in shaping the persistence of monetary policy effects on poor regions. For instance, with weak fiscal risk sharing, these regions suffer from a durable output contraction in response to a policy rate hike. By contrast, with strong fiscal risk sharing, poor regions do not only face a weaker output contraction, but are also insulated from such hysteresis effects.

Third, private and public risk-sharing channels act as complements in terms of their respective time profiles. The private channels, operating via credit and factor markets, attenuate the real effects of monetary policy over a horizon of up to two years. Public risk sharing, operating via the fiscal transfer and tax system, instead does not produce significant differences in monetary policy transmission over this period. But it then kicks in over longer horizons, just when the private risk-sharing channels lose effectiveness.
These findings offer relevant insights for the debate on the institutional setup of the Economic and Monetary Union (EMU). First, they suggest that heterogeneity in the capacity to absorb shocks via fiscal and market-based channels could contribute to an uneven transmission of monetary policy. From that point of view, it appears desirable to strive for a harmonised risk-sharing architecture in a currency union. Second, the results point to the benefits of fiscal risk sharing in mitigating the tendency for regional economic divergence to intensify in policy tightening cycles. Third, they indicate that changes to the risk-sharing architecture of an economy may have a major bearing on the aggregate effects of a given change in monetary policy stance.

Related Literature. Our analysis places itself at the intersection of two important strands of the literature. The first relates to the quantification of risk sharing within and across countries (Mace, 1991; Cochrane, 1991; Townsend, 1994). In the seminal approach to this literature, Asdrubali et al. (1996) propose a framework based on decomposing the cross-section of shocks to the GDP of US states to quantify the role of private and public risk-sharing channels in smoothing out idiosyncratic shocks. This framework has also been applied to other jurisdictions, including individual euro area countries (e.g. Buettner, 2002; Hepp and von Hagen, 2013 for Germany). While the resultant estimates of intranational risk sharing lie in a similar range as those for the United States (Burriel et al., 2020), risk sharing between euro area countries has been found to be significantly lower (Sorensen and Yosha, 1998). At the same time, more recent papers suggest that the amount of international risk sharing in the euro area has risen in the aftermath of the sovereign debt crisis (Cimadomo et al., 2020) and may be further enhanced with deeper fiscal integration (Furceri and Zdzienicka, 2015).

To shed light on how risk sharing interacts with monetary policy transmission, we connect to a second strand of the literature. Starting from the vast body of evidence on the aggregate effects of monetary policy, a growing number of papers have highlighted that the transmission of monetary policy is heterogeneous within a given economy. Applying these insights to the geographical dimension, there is also in-
creasing evidence that the regional incidence of monetary policy differs depending on initial conditions and economic structures (Cœuré, 2018). For instance, Hauptmeier et al. (2020) document that the output response to euro area monetary policy shocks is stronger and more persistent for poorer regions, and similar studies for the US economy point to heterogeneity in transmission for instance due to differences in local mortgage market conditions (Neville et al., 2012; Fratantoni and Schuh, 2003; Di Maggio et al., 2017; Beraja et al., 2019). Our paper is the first to integrate risk sharing into an empirical analysis of monetary policy transmission.

The remainder of the paper proceeds as follows. The next section describes the data and highlights some salient stylized facts regarding economic activity at the regional level. Section 3 presents the estimates of the degree of risk sharing in euro area countries. The interaction between risk sharing and monetary policy is analysed in Section 4. Section 5 documents a range of robustness checks and Section 6 concludes.

2 Data and stylized facts

We rely on regionally disaggregated economic data based on Eurostat’s Nomenclature of Territorial Units for Statistics (NUTS). The NUTS classification breaks down the EU Member States into four levels. The highest level (NUTS-0) corresponds to the nation state. The lower levels (NUTS-1 to NUTS-3) subdivide national territories into ever more granular units based on population thresholds and existing administrative structures. Our analysis uses NUTS-2 data, which offer the most granular regional breakdown with sufficient variable coverage to estimate the degree of risk sharing within each country (see Section 3). NUTS-2 regions are defined as hosting between 800,000 and 3,000,000 inhabitants and typically refer to Provinces, Regions and, in some cases, States.

The analysis considers the founding members of the euro area, plus Greece, while

---

7For example, German NUTS-2 level regions correspond to the Regierungsbezirk. Similarly, in France (until 2015), NUTS-2 level regions correspond to the Régions; in Italy to the Regioni; in Spain to the Comunidades y ciudades Autónomas; in the Netherlands to the provincies; and in Austria to the Bundesländer.
excluding Luxembourg and Ireland due to the low number of NUTS-2 regions in the latter two countries.\footnote{Luxembourg and Ireland contain only 1 and 3 NUTS-2 regions, respectively. The sample for Greece starts in 2001 because this is when the country introduced the euro. In 2014, the French parliament passed a law reducing the number of metropolitan regions from 22 to 13. We conserve the former territorial division of 22 NUTS-2 regions. We also follow the literature in excluding NUTS-2 regions of the French overseas territories of Guadeloupe, Martinique, French Guiana, La Réunion and Mayotte, along with the Portuguese autonomous regions of the Azores and Madeira (Becker et al., 2010).} Our final sample thus consists of 155 regions from 10 Euro area countries over the period 2000-2018 at annual frequency.

The main regional variables of interest are gross domestic product (GDP), primary income, disposable income, and consumption. The source of the first three variables is Eurostat’s regional statistics database. Regional consumption instead comes from the European Cities and Regions database of Oxford Economics. All variables are deflated to 2015 Euros, using the regional deflator from the European Commission’s ARDECO database, and are expressed in per capita terms. We complement this regionally disaggregated information with euro area and country level variables to control for aggregate economic and financial conditions (see Section 4 and Annex C).

The data reveal two key facts that motivate the ensuing analysis. First, there is substantial heterogeneity in economic output across and within euro area countries (Table 1). In 2018, for instance, average per capita GDP at the NUTS-2 level ranged from 14,495€ in Greece to 41,128€ in Austria. Moreover, also within countries, per capita GDP exhibits pronounced dispersion, with some countries displaying a higher coefficient of variation (CV) than the euro area as a whole.

Second, the degree of regional dispersion within countries tends to fall as we turn from GDP to primary income, disposable income, and ultimately consumption. On average, the regional CV for GDP is 2.5 times as high as that for consumption. By contrast, the corresponding figure amounts to only 1.3 for the euro area. This pattern points to powerful forces that weaken the link between regional output and consumption spending within countries. In the following section, we shed light on these forces through the lens of their risk-sharing properties, before exploring their interaction with monetary policy transmission in Section 4.

**Note**: Figures refer to real per capita GDP, primary income, disposable income and consumption in 2018 at the NUTS-2 level, except for the euro area row, which is based on NUTS-0 (country-level) data. The coefficient of variation (CV) is computed as the ratio of the standard deviation to the mean of all NUTS-2 (NUTS-0) units within each country (the euro area) in 2018.

### 3 Risk sharing in euro area countries

Following Asdrubali et al. (1996), we identify three channels of risk sharing: the factor market channel, the fiscal channel, and the credit market channel. To this end, we estimate the following panel regressions for each euro area country at the NUTS-2 level, using annual data from 2000 to 2018:

1. \[ \Delta^j gd p^k_t = \beta_{K,j} \times \Delta^j gd p^k_t + \alpha_{K,j} + \epsilon^k_{K,j} \quad \text{(Factor market channel)} \]  
2. \[ \Delta^j p^k_t = \beta_{F,j} \times \Delta^j gd p^k_t + \alpha_{F,j} + \epsilon^k_{F,j} \quad \text{(Fiscal channel)} \]  
3. \[ \Delta^j d^k_t - \Delta^j c^k_t = \beta_{C,j} \times \Delta^j gd p^k_t + \alpha_{C,j} + \epsilon^k_{C,j} \quad \text{(Credit market channel)} \]  
4. \[ \Delta^j c^k_t = \beta_{U,j} \times \Delta^j gd p^k_t + \alpha_{U,j} + \epsilon^k_{U,j} \quad \text{(Unsmoothed)} \]

\(^9^{See Annex A for additional detail on the methodology. We use the terms fiscal and public risk sharing as synonyms and occasionally refer to the factor and credit market channels as private risk sharing.\)
where \( gdp_t^k \) denotes the log of real per capita output in region \( k \) in period \( t \), and \( pi_t^k, dt_t^k \) and \( c_t^k \) are the corresponding variables for primary income, disposable income, and consumption of private households, respectively. \( \alpha_{x,t} \) are time fixed-effects and \( \varepsilon_{x,t} \) are the error terms. As the degree of risk sharing through either of the channels may vary with the persistence of the underlying GDP fluctuations, we estimate these equations over alternative time-differencing intervals, such that \( \Delta^j x_t^k = x_t^k - x_{t-1-j}^k \), with \( j = 0, ..., 5 \) (Asdrubali et al., 1996; Athanasoulis and van Wincoop, 2001). The equations are estimated via OLS, with standard errors clustered at the regional level and bootstrapped.

The wedge between output and primary income corresponds to the net income streams receivable from and payable to other regions and countries; these may originate either from capital, due to internationally or inter-regionally diversified private investment portfolios (e.g. yielding dividend payments); or from labour, due to the compensation accruing to commuters who work in a region or country other than their place of residence.\(^{10}\) Accordingly, \( \beta_{K,j} \) measures the amount of risk sharing achieved through the factor market channel.

The wedge between primary and disposable income stems from the difference between tax payments to and transfer payments from the government; \( \beta_{F,j} \) thus measures the fraction of shocks smoothed by the fiscal channel.

Finally, the wedge between disposable income and consumption reflects economic agents’ debt accumulation minus savings in each period, so that \( \beta_{C,j} \) measures the inter-temporal risk sharing via credit markets. The amount of unshared risk in the

\(^{10}\) The wedge between output and primary income is analogous to the difference between GDP and GNI in national accounting. As in national accounting, regional GDP is recorded where it is generated (the place of work), while income is recorded in the place of residence of the worker. The wedge between the two therefore captures net income earned abroad, i.e. from a different country or a different region. Factor income coming from labour is larger at the regional than at the national level as commuting is more common between regions, particularly for smaller regions and around metropolitan centres (Eurostat, 2021). As a result, the size and composition of this wedge may also differ noticeably within countries. In 2018, for instance, the ratio of primary income to GDP was particularly low in capital regions, such as Région de Bruxelles-Capitale/Brussels Hoofdstedelijk Gewest (34.1%) in Belgium. By contrast, this ratio was significantly larger in other regions, such as Schleswig-Holstein in Germany (83.0%) or Burgenland (87.6%) in Austria.
economy, in turn, is given by $\beta_{U,j}$, so that the $\beta$-coefficients jointly satisfy:

$$\beta_{K,j} + \beta_{F,j} + \beta_{C,j} = \beta_{S,j} = 1 - \beta_{U,j}$$

(5)

where $\beta_{S,j}$ is the total amount of risk sharing in a given region.

The estimates of equations (1)-(4) document substantial cross-country heterogeneity in risk-sharing patterns (Figure 1 and Annex Tables B1-B2). Factor markets generally emerge as the dominant channel in smoothing out contemporaneous fluctuations in GDP (i.e. setting $j = 0$): the respective point estimates, $\hat{\beta}_{K,0}$ are highly significant and exceed $\hat{\beta}_{F,0}$ and $\hat{\beta}_{C,0}$ by a substantial margin in most countries. At the same time, the cross-country distribution of $\hat{\beta}_{K,0}$ covers a broad range, which we exploit in Section 4 to study the interaction between varying risk-sharing intensities and monetary policy transmission. Likewise, the estimates for the other two channels exhibit pronounced cross-country heterogeneity, while presenting a more uneven picture in terms of relative strength and precision.

The persistence of the regional GDP fluctuations proves particularly relevant for smoothing via the factor market and fiscal channels. The former declines as the time-differencing interval increases. In fact, after five years almost the entire cross-country distribution lies to the left of that for the contemporaneous coefficients (see red dashed and blue solid lines in Figure 1a). By contrast, fiscal risk sharing tends to intensify for higher time-differencing intervals, albeit insufficiently so to prevent a rise in the unsmoothed portion (Figures 1b and 1d); and, in most countries, $\beta_{F,j}$ turns significant over longer horizons. Consistent with the findings in Asdrubali et al. (1996), this pattern points to a sluggish response of the smoothing mechanisms working via the government sector.

\[\text{11}\text{The prominent risk-sharing contribution of factor markets is consistent with previous studies. For instance, Hepp and von Hagen (2013) document that factor markets accounted for more than 50\% of risk sharing across German States in the post-reunification period.}\]
Figure 1: Cross-country densities of estimated risk-sharing coefficients

(a) Factor market channel
(b) Fiscal channel
(c) Credit market channel
(d) Unsmoothed

Note: Blue solid (red dashed) lines show the cross-country density functions of the $\beta$-coefficients estimated in equations (1)-(4) for $j = 0$ ($j = 5$). The former (latter) correspond to the amount of risk sharing achieved contemporaneously (over a five-year horizon). The full set of estimates is reported in Tables B1-B2.

4 Risk sharing and monetary policy transmission

In this section, we study how the degree of risk sharing in an economy affects the transmission of monetary policy to the real economy. To this end, we first set up a benchmark local linear projections model to estimate the dynamic effect of monetary policy on regional output. We then augment this model with the estimated parameters reported in Section 3 to assess the implications of risk sharing for the real effects of monetary policy. Third, we break down the impact of risk sharing into its private and public channels. Finally, we study whether the impact of specific risk-sharing channels differs across poorer and richer regions.
4.1 Baseline model

As a starting point, we follow Hauptmeier et al. (2020) in estimating the dynamic effects of monetary policy on regional output. We apply Jordà (2005)’s local projections method consisting in a set of regressions of the form:

\[ y_{k,t+h} = \alpha_k + \kappa_i i_t + \gamma_k X_{k,t} + \delta_h X_{c,t} + \theta_h X_t + \varepsilon_{k,t+h} \]  \hspace{1cm} (6)

where the dependent variable \( y_{k,t+h} \) denotes real GDP (in logs) in jurisdiction \( k \) and year \( t+h \); \( \alpha_k \) is a set of region-fixed effects; \( i_t \) is the monetary policy-controlled short-term interest rate in year \( t \) and enters equation 6 as a percentage per annum;\(^{12}\) \( X_{k,t}, X_{c,t}, \) and \( X_t \) are vectors of time-variant control variables at the regional, country and euro area level, respectively (see Table C1); and \( \varepsilon_{k,t+h} \) is an error term.

At the regional level, we control for the population (in log) of each NUTS-2 unit. At the country level, we control for: (i) financial conditions, captured by stock market indices (in log) and the 10-year government bond yield; and (ii) fiscal positions, captured by the government debt ratio and the change in the structural primary balance. The euro area controls include GDP and HICP (both in log) as standard elements of the monetary policy reaction function.

Controlling for aggregate macroeconomic conditions, monetary policy should be exogenous to variation in regional GDP, which serves as our main identification assumption. As discussed in Hauptmeier et al. (2020), this assumption is supported by: (i) the ECB’s mandate pertaining to the euro area level (ECB, 1998); (ii) the small size of individual regions relative to the euro area economy as a whole;\(^{13}\) and (iii) the long publication lags for regional data, which become available only around two to three years after the period they refer to and, as such, are not part of the policy-relevant information set in real-time. In Section 5 we also subject this identification assumption

---

\(^{12}\)Following the literature, we use the 3-month Euribor as our measure of the policy-controlled short-term interest rate (e.g. Smets and Wouters, 2003). The data for this variable come from the Area Wide Model (AWM) database. To better capture the impact of non-standard measures affecting the policy stance in the final years of the estimation period, we extend the short-term interest rate from 2014 by adding the cumulative changes of the shadow interest rate developed by Lemke and Vladu (2017).

\(^{13}\)For example, while Lombardia’s GDP accounted for 22% of Italian GDP in 2018, it represented only 3.5% of euro area GDP.
to a range of robustness checks.

We estimate equation 6 by ordinary least squares (OLS) for \( h = 0, \ldots, 5 \). Inference is based on Driscoll and Kraay (1998) standard errors that account for cross-sectional and temporal dependencies in the data. The results are presented as the response of regional output to a 100 basis point hike in the short-term interest rate in year \( t \), captured by the coefficient \( \kappa_h \) for each horizon \( h \).

As depicted by the impulse response function (IRF) in Figure 2, regional output contracts after a monetary policy tightening. The impact reaches its peak at the two-year horizon, with the IRF implying a contraction of around 2%, followed by a gradual recovery over the remainder of the horizon. These estimates are consistent with the related literature on the real effects of monetary policy (e.g. Smets and Wouters, 2003) and with previous studies using regional data for the euro area (e.g. Hauptmeier et al., 2020).

Figure 2: Impact of monetary policy on regional GDP

Note: Vertical axis refers to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axis refers to the horizon of the IRF (in years). Solid line denotes point estimates and shaded area denotes 90% confidence bands.
4.2 Interaction between risk sharing and monetary policy

We now turn to the question on how risk sharing interacts with monetary policy transmission. To this end, we augment the baseline model (equation 6) with the risk-sharing estimates from Section 3, which yields:

\[ y_{k,t+h} = \alpha_{k,h} + \left( \kappa_{0,h} + \kappa_{S,h} \times \hat{\beta}^{c}_{S,h} \right) i_t + \gamma_{h} X_{k,t} + \delta_{h} X_{c,t} + \theta_{h} X_{t} + \varepsilon_{k,t+h} \]  

(7)

where \( \hat{\beta}^{c}_{S,h} \) is the amount of risk sharing achieved in country \( c \) after \( h \) periods. Because they are estimated from the data, the \( \hat{\beta}^{c}_{S,h} \) coefficients are generated regressors and have their own sampling variance (Pagan, 1984; Murphy and Topel, 1985). We thus follow the literature and bootstrap both stages of the analysis (i.e. the estimation of risk sharing in Section 3 and the estimation of the local projections as per equation 7) to adjust the standard errors. The Driscoll and Kraay (1998) standard errors are therefore bootstrapped. We use the same control variables as in the baseline model.

To facilitate interpretation, we standardize the \( \hat{\beta}^{c}_{S,h} \) coefficients for each country \( c \) by demeaning and dividing it by its cross-country standard deviation. Thus, the coefficient \( \kappa_{0,h} \) captures the response of regional output in period \( t + h \) to a change in the short-term interest rate in period \( t \) when risk sharing is at the average of the sample. The coefficient \( \kappa_{S,h} \) shows whether and how this impact varies with the degree of risk sharing. Taken together, these coefficients summarize the impact of a 100 basis point monetary policy rate hike at each horizon \( h \) conditional on the degree of risk sharing in country \( c \) as:

\[ \frac{\partial y_{k,t+h}}{\partial i_{t}} = \kappa_{0,h} + \kappa_{S,h} \times \hat{\beta}^{c}_{S,h} \]  

(8)

We report the estimation of equation 7 in Table 2. The interaction term between the monetary policy interest rate and risk sharing is positive and statistically significant for the entire horizon. Hence, our results indicate that risk sharing dampens the real effects of monetary policy. To highlight the economic relevance of this dampening effect, Figure 3 presents the response of regional output to a 100 basis point interest rate hike for different percentiles of the risk-sharing distribution. At the upper
quartile of the distribution, regional output decreases by 1.9% after two years. This is 0.4 percentage point higher than when risk sharing is at the lower quartile of the distribution (Figure 3a).

The Driscoll and Kraay (1998) standard errors are bootstrapped using 1000 iterations.

Further, these differences in the output response intensify when considering the outer parts of the risk-sharing distribution. For instance, the GDP trough for the lower
decile (again materialising in year \( t + 2 \)) is 1.1 percentage points lower than the corresponding trough for the upper decile (Figure 3b). Moreover, the persistence of the GDP contraction differs markedly across the distribution. At high degrees of risk sharing, output recovers to its pre-shock levels by the end of the horizon. At low degrees of risk sharing, the contractionary effect of monetary policy instead proves persistent and output remains depressed even five years after the shock. In sum, by smoothing out the output losses in individual regions, risk sharing also weakens the average effects of monetary policy on the economy and renders regional GDP less susceptible to hysteresis effects (Blanchard, 2018).

### 4.3 Disentangling private and public risk sharing effects

We next examine the contribution of individual risk-sharing channels in shaping monetary policy transmission. We hence replace \( \hat{\beta}_{5,h} \) by its components, as listed in equation 5, to estimate the following model:

\[
y_{k,t+h} = \alpha_{k,h} + \left( \kappa_{0,h} + \kappa_{K,h} \times \hat{\beta}_{K,h} + \kappa_{F,h} \times \hat{\beta}_{F,h} + \kappa_{C,h} \times \hat{\beta}_{C,h} \right) i_t + \gamma_h X_{k,t} + \delta_h X_{c,t} + \theta_h X_t + \epsilon_{k,t+h}
\]

where \( \hat{\beta}_{K,h} \), \( \hat{\beta}_{F,h} \), \( \hat{\beta}_{C,h} \) are the amount of risk sharing achieved in country \( c \) after \( h \) periods through the factor market channel, the fiscal channel, and the credit market channel, respectively. As in equation 7, the \( \beta \)-coefficients are standardized and the results refer to the impact of a 100 basis point rate hike. The control variables are the same as in regressions 6 and 7.

The significant and positive interaction terms imply that both, private risk sharing via factor and credit markets, as well as public risk sharing, cushion the impact of a monetary policy tightening (Table 3). However, the channels differ in their time profiles. Private risk-sharing channels tend to dampen the monetary policy shock contemporaneously and up to one year after the shock. For example, Figure 4a (Figure 4c) shows that regional output drops by around 0.9\% (0.8\%) after one year when the degree of risk sharing through factor (credit) markets is in the upper quartile of the
Table 3: Baseline estimates for coefficients on the short-term interest rate and the interaction with the fraction of shared risk.

Note: This table reports the estimates of equation 9. $\hat{\beta}^h_{K,h}$, $\hat{\beta}^h_{F,h}$, $\hat{\beta}^h_{C,h}$ are standardized. The Driscoll and Kraay (1998) standard errors are given in parenthesis. Standard errors are bootstrapped using 1000 interactions. * / ** / *** indicate 1% / 5% / 10% significance level.

distribution. Instead, the contraction is significantly more pronounced, reaching close to 1.6% (2.1%), when risk sharing through these channels is in the lower quartile. After two years, however, the dampening impact of risk sharing through factor and credit markets fades away.

Fiscal risk sharing instead tends to dampen the economic consequences of a rate hike over longer horizons (Figure 4b). While differences in the point estimates are not statistically significant up to $t + 1$, the IRFs as well as the confidence bands diverge as of $t + 2$. When fiscal risk sharing is in the upper quartile, regional output drops by slightly less than 1.8% in year $t + 2$ and recovers to its initial level after five years. By contrast, the estimates point to a sharper contraction when fiscal risk sharing is in the lower quartile, reaching 2.4% after two years. Moreover, at the end of the horizon, output remains depressed, still standing 1.3% below its level prior to the shock in economies with weak fiscal risk sharing.

The diverse time profiles across private and public channels appear consistent with the findings of Asdrubali et al. (1996). One may argue that credit markets offer a well-established and timely avenue for private agents to smooth out fluctuations in income distribution.
Figure 4: Impact of monetary policy on regional output when risk is shared through the different channels

(a) Factor market channel  
(b) Fiscal channel  
(c) Credit market channel

Note: Vertical axes refer to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axes refer to the horizon of the IRFs (in years). Solid lines denote point estimates and shaded areas denote 90% confidence bands. Red (blue) lines depict the estimates for the upper (lower) quartiles of $\beta_{K,h}$, $\beta_{F,h}$ or $\beta_{C,h}$. The Driscoll and Kraay (1998) standard errors are bootstrapped using 1000 iterations.

over the economic cycle, e.g. by borrowing from banks. However, as downturns become more persistent, banks will gradually pare back their lending activity due to declining creditworthiness, which in turn lowers the respective risk-sharing contribution over time. Similarly, cross-regional income flows would initially be unaffected by a downturn in a specific economy, thus supporting the factor market channel in the initial years after the shock. But as the downturn drags on, households may be forced e.g. to divest their international asset holdings, thus foregoing the respective future...
income streams. As a consequence, also the factor market channel loses potency as the downturn persists.

The gradual phasing-in of public risk sharing, as visible in Figure 1b and Table B1, is in line with the findings of Asdrubali et al. (1996) and Buettner (2002) and consistent with the usual lags in the fiscal response to changing economic circumstances. As a result, the fiscal risk-sharing channel shows up significant only from year \( t + 2 \) onward. But it then leads to a materially faster recovery and prevents the persistent contraction in output arising in regions with a low level of fiscal risk sharing.

Overall, our estimates point to complementarities between private and public risk-sharing channels over time. While private risk sharing tends to dampen the effects of a monetary policy shock in the short-run, public risk sharing tends to limit adverse regional output effects over longer horizons and to prevent long-lasting hysteresis effects.

### 4.4 Heterogeneity across regions

We next explore whether the interaction of risk sharing with the transmission of monetary policy varies between poor and rich regions. Given its explicit redistributive character, we mainly focus on the fiscal risk sharing channel. Even without inequality across economic agents, fiscal instruments may attenuate disposable income fluctuations and thereby stabilize consumption and output (Brown, 1955). But the stabilization role of fiscal policy may be reinforced in the presence of heterogeneity, if net transfers are targeted towards agents with a larger marginal propensity to spend (Blinder, 1975), which tend to concentrate in the lower parts of the income distribution (Parker et al., 2011). As documented by McKay and Reis (2016) for the US economy, the stabilizing properties of fiscal policy indeed mainly derive from its effects in mitigating household inequality and its social insurance function. As poorer geographical units tend to host a larger share of vulnerable households and firms (Hauptmeier et al., 2020), these mechanisms may also operate at the regional level.

To quantify the dynamic impact of exogenous changes in monetary policy across the regional GDP distribution for different levels of risk sharing, we combine Jordà
(2005)’s local projections method with quantile estimation techniques. First introduced by Koenker and Bassett (1978), quantile regression models characterize the entire conditional distribution of a dependent variable conditional on a set of regressors. These models therefore also provide a flexible way to explore heterogeneity in the response to monetary policy and its interaction with risk sharing. However, in the presence of fixed effects, quantile estimation suffers from incidental parameter problems (Lancaster, 2000). To address this issue, we employ the quantiles-via-moments estimator proposed by Machado and Santos Silva (2019) to estimate panel data models with individual fixed effects. This approach enables us to control for unobserved heterogeneity while estimating quantile-specific coefficients of the covariates in our model via location- and scale-functions.

Figure 5: Impact of monetary policy on regional output of poor and rich regions with high or low levels of fiscal risk sharing

![Figure 5](image)

(a) Effect on poor regions  
(b) Effect on rich regions

**Note:** Vertical axes refer to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axes refer to the horizon of the IRFs (in years). Solid lines denote point estimates and shaded areas denote 90% confidence bands. Red (blue) lines depict the estimates for the upper (lower) deciles of $\hat{\beta}_{F,h}$ in poor (10th percentile) and rich (90th percentile) regions. Standard errors are clustered at the time and regional level and are bootstrapped using 1000 iterations.

---

14In the quantile regressions, we again account for potential error correlation across space and time. To this end, we resort on two-way clustering, given the Discoll-Kraay correction used for the mean regressions is not available for the quantile estimator. As highlighted by Machado and Santos Silva (2019), the estimator might be biased when the number of cross-sectional units is large relative to the time periods. As a robustness check, we thus use the split-sample jackknife bias correction of Dhaene and Jochmans (2015) to address this potential issue and confirm that our results remain intact.
Our quantile regression analysis reveals pronounced differences in the degree to which fiscal risk sharing shapes the transmission of monetary policy to rich versus poor regions (defined here as the upper and lower decile of the conditional GDP distribution). With weak fiscal risk sharing, GDP in poor regions does not only exhibit a strong contraction, but the impact proves highly persistent (Figure 5a): five years after the shock, GDP still remains around 2% below its initial level. By contrast, with strong fiscal risk sharing, the GDP contraction in poor regions is markedly shallower and turns insignificant at horizon $t + 4$. For rich regions, stronger fiscal risk sharing also damps the real effects of monetary policy (Figure 5b). But the difference in the strength and, especially, the persistence of these effects across risk-sharing levels is much less accentuated than for poor regions. As such, fiscal risk sharing emerges as particularly instrumental in preempting long-lived ‘hysteresis’ effects of monetary policy in regions with weak economic performance already prior to the shock.

5 Robustness

In this section, we perform a number of robustness checks of our baseline estimations. First, we rerun them without the 20 largest regions for each year in our sample (Figure 7 in Annex E.1). This allows us to account for the possibility that monetary policy decisions are not entirely independent of economic conditions in regions that carry a particularly large weight in aggregate GDP. The estimated coefficients remain very close to our baseline results, thus supporting our initial assumption that regional conditions, even for the largest regions, do not enter the central bank reaction function.

A second robustness check aims to reinforce our main identification assumption by explicitly controlling for regional heterogeneity in the local projections model. Recent evidence for the United States has highlighted that the Federal Reserve indeed

---

15 This evidence on long-lived real effects of monetary policy in poor regions echoes similar findings in Hauptmeier et al. (2020).

16 As an interesting aside, the factor- and credit-market channels, if anything, operate more forcefully in the upper part of the GDP distribution (Figure 6 in Annex D). Although the patterns are not as clear-cut as for fiscal risk sharing, this result appears consistent with the non-redistributive nature of these two channels and with the notion that the ability to build diversified asset portfolios and to maintain easy access to credit markets concentrates in the higher quantiles of the income distribution.
reacts to regional disparities in its interest-rate setting (Coibion and Goldstein, 2012). If confirmed for the euro area, these regularities would cast doubt on our identifying assumption that, controlling for aggregate economic conditions, monetary policy is exogenous to regional GDP. We hence calculate a set of regional economic dispersion measures and test whether they exhibit significant explanatory power in a standard monetary policy reaction function. Following Coibion and Goldstein (2012), the dispersion measures comprise: (i) the population-weighted variance of per-capita regional GDP, (ii) the difference between GDP of the 90th and 10th percentiles of the cross-sectional distribution of regional output at time $t$, and (iii) the equivalent measure for the 80th and 20th percentiles. None of these dispersion measures carries a significant coefficient in the estimated policy reaction function.\footnote{As in Coibion and Goldstein (2012), the reaction function defines the short-term interest rate as the dependent variable and, as explanatory variables, includes the first lag of the dependent variable, along with euro area GDP growth and inflation, as well as the first lag of the respective dispersion measures.} Since the absence of significant coefficients may also reflect the low number of observations in our time sample (amounting to just 18 data points), we also conduct additional exercises including each of the dispersion measures as an additional covariate in the local projections model. Again, this modification to our baseline model leaves our results intact.\footnote{Impulse response functions are available upon request.}

Third, we check the robustness of our results with respect to the use of different shadow rate measures. The pronounced model uncertainty in deriving shadow rates has given rise to a large dispersion of estimates available in the literature (Figure 8 in Annex E.2). We hence replace our baseline measure, as described in footnote 12, with two alternatives, namely the ones developed by Krippner (2015) and by Wu and Xia (2017). Again, our results are robust to these alternative options (Figure 9 in Annex E.2).

To guard against omitted variable bias, we also extend our baseline model with a set of factors that may be correlated with both regional activity and policy rates. Specifically, we include global oil prices and the real effective exchange rate against major trading partners as they often feature in ECB policy communication and are likely to have different effects on a given region depending on its economic structure (e.g. House et al., 2020). The inclusion of these two variables yield impulse response functions available upon request.
functions close to our baseline estimations (Figure 10 in Annex E.3).

Monetary policy decisions may not only react to current macroeconomic conditions but also to the expected realizations of economic activity and prices. We hence conduct another set of robustness checks, relying on the quarterly ECB staff macroeconomic projections to construct forward-looking versions of these variables. To this end, we compute the average of the two-year projections across the four projection vintages of each year (see Appendix E.4 for further detail). Since medium-term macroeconomic projections are highly correlated with current economic developments, we replace the contemporaneous variables for euro area GDP and prices by its medium-term projections to avoid multicollinearity issues. Again, the estimates remain largely unchanged compared with our benchmark results (Figure 11).

As a final robustness check, we follow Ramey (2016) and include the lagged residual of the (shadow) short-term interest rate as an additional control variable in the local projections. This way, we account for serial correlation in the exogenous policy rate changes, which could raise concerns about their unanticipated nature. The estimated IRFs suggest a similar contraction in output for both high and low levels of risk sharing, albeit with somewhat lower persistence, as in the baseline (Figure 12 in Annex E.5).

6 Conclusion

This paper explores the interaction between risk sharing and monetary policy, exploiting granular data on economic activity in euro area regions. Our estimates show that the strength and channels of risk sharing vary across euro area countries, and that this variation affects the transmission of monetary policy. First, we find that risk sharing shapes the real effects of monetary policy shocks. Regions attaining a high degree of risk sharing experience a significantly shallower contraction in output after a policy rate hike and are less prone to policy-induced hysteresis. Second, public risk sharing especially benefits poor regions by shielding them against hysteresis effects. Third, fiscal and market-based risk-sharing channels emerge as complements in that they
operate at different time horizons.

These findings speak to an active policy debate on the merits of deeper fiscal and financial integration in the euro area (Bénassy-Quéré et al., 2018). In this context, it has been argued that increased risk sharing would strengthen the euro area’s resilience to economic shocks (Draghi, 2018; Lane, 2021). Our empirical analysis provides support to this notion in that it highlights the benefit of risk sharing in mitigating adverse hysteresis effects in policy tightening cycles. At the same time, it also indicates that the degree and composition of risk sharing has a bearing on how strongly monetary policy needs to be adjusted in order to achieve a given effect on economic activity.
References

A Methodology to estimate the degree of risk-sharing

We follow Asdrubali et al. (1996) and decompose the cross-sectional variance of shocks to GDP by first considering the following identity, holding for any period $t$:

$$\text{GDP}^k = \frac{\text{GDP}^k \text{PI}^k \text{DI}^k \text{C}^k}{\text{PI}^k \text{DI}^k \text{C}^k}$$ (10)

where all the magnitudes are in per capita terms and $k$ is an index of regions. To emphasize the cross-sectional nature of our derivation, we abstract from the time index. GDP denotes regional gross domestic product. PI, DI and C denote, for private households, primary regional income, disposable regional income and regional consumption respectively.

Taking logs and differences of the identity 10, multiply both sides by $\Delta \log \text{GDP}$, and take the cross-sectional average to obtain the variance decomposition:

$$\text{var}\{\Delta \log \text{GDP}\} = \text{cov}\{\Delta \log \text{GDP}, \Delta \log \text{GDP} - \Delta \log \text{PI}\}$$
$$+ \text{cov}\{\Delta \log \text{GDP}, \Delta \log \text{PI} - \Delta \log \text{DI}\}$$
$$+ \text{cov}\{\Delta \log \text{GDP}, \Delta \log \text{DI} - \Delta \log \text{C}\}$$
$$+ \text{cov}\{\Delta \log \text{GDP}, \Delta \log \text{C}\}$$ (11)

Dividing by $\text{var}\{\Delta \log \text{GDP}\}$ yields the following equation:

$$\beta_K + \beta_F + \beta_C = 1 - \beta_U$$ (12)

which corresponds to equation 5 for $j = 0$, where, for example:

$$\beta_K = \text{cov}\{\Delta \log \text{GDP}, \Delta \log \text{GDP} - \Delta \log \text{PI}\} / \text{var}\{\Delta \log \text{GDP}\}$$

$\beta_K$ is the ordinary least squares estimate of the slope in the cross-sectional regression of $\Delta \log \text{GDP}$ on $\Delta \log \text{GDP} - \Delta \log \text{PI}$ (equation 1 for $j = 0$), and similarly for $\beta_F$ (equation 2), $\beta_C$ (equation 3), and $\beta_U$ (equation 4).

D  Inequality and risk-sharing

Figure 6: Impact of monetary policy on output of poor vs rich regions when risk is shared through private risk-sharing channels

Factor market channel

(a) Effect on poor regions (10th pct)  
(b) Effect on rich regions (90th pct)

Credit market channel

(c) Effect on poor regions (10th pct)  
(d) Effect on rich regions (90th pct)

Note: Vertical axes refer to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axes refer to the horizon of the IRFs (in years). Solid lines denote point estimates and shaded areas denote 90% confidence bands. Red (blue) lines depict the estimates for the upper (lower) deciles of $\hat{\beta}_{K,h}^c$ and $\hat{\beta}_{C,h}^c$. Standard errors are clustered at the time and regional level and are bootstrapped using 1000 iterations.
E Robustness checks

In this section, we report the impulse response functions of the robustness checks described in Section 5.

E.1 Excluding the largest regions from the sample

Figure 7: Impact of monetary policy on regional aggregates when excluding the largest regions

Note: Vertical axis refers to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axis refers to the horizon of the IRF (in years). Solid lines denote point estimates and shaded areas denote 90% confidence bands. The 20 largest regions are excluded for each year.
E.2 Alternatives for the shadow interest rate

Figure 8: Shadow rates for the Euro area

Note: The short-term interest rate (STN) is extended by adding the cumulative changes of the shadow rates developed by Lemke and Vladu (2017), Krippner (2015) and Wu and Xia (2017)
Figure 9: Impact of monetary policy on regional output using different monetary policy rates

(a) Short-term interest rate
(b) Lemke and Vladu (2017)
(c) Krippner (2015)
(d) Wu and Xia (2017)

Note: Vertical axes refer to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axes refer to the horizon of the IRFs (in years). Solid lines denote point estimates and shaded areas denote 90% confidence bands. The short-term interest rate (STN) is extended by adding the cumulative changes of the shadow rates developed by Lemke and Vladu (2017), Krippner (2015) and Wu and Xia (2017)
E.3 Adding oil prices and the real effective exchange rate

Figure 10: Impact of monetary policy when risk is shared with oil prices and REER

Note: Vertical axes refer to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axes refer to the horizon of the IRFs (in years). Solid lines denote point estimates and shaded areas denote 90% confidence bands. Red (blue) lines depict the estimates for the upper (lower) quartiles of $\beta_c^S, \beta_c^K, \beta_c^F$ or $\beta_c^C$. The Driscoll and Kraay (1998) standard errors are bootstrapped using 1000 iterations.
E.4 Forward-looking variables

We construct the forward-looking indicators for GDP and HICP from the quarterly ECB staff macroeconomic projections (see Hauptmeier et al. (2020) for further details). While these projections are a staff-level exercise that does not necessarily have to fully match the Governing Council’s assessment of the economic outlook, they are an integral element of the Governing Council’s information set. We compute the average across the four projection vintages of each year for two years ahead. For most of the sample period, the horizon of the March, June, and September projection vintages of year t stretched until year t + 2. To do so, we first calculate a forward-looking inflation variable as:

$$
\pi_{t+2|t} = \frac{1}{4} (\pi_{t+2|DEC,t-1} + \pi_{t+2|MAR,t} + \pi_{t+2|JUN,t} + \pi_{t+2|SEP,t})
$$

where $\pi_{t+2|t}$ is the expected inflation rate for year $t + 1$ entering the central bank information set in year $t$, $\pi_{t+2|X,t-1}$ is the expected annual inflation rate in year $t + 2$ according to the ECB macroeconomic projections in month X. The forward-looking variable for the rate of real economic growth is calculated in analogous fashion. We then compute the expected level of HICP using the respective inflation rate in year $t$ and 2015 as the reference year (2015 = 100). Similarly, we calculate the expected level of GDP using the projected level of GDP in 2015. Consistent with the baseline specification, expected HICP and GDP are expressed in 100 times their log-levels.
Figure 11: Impact of monetary policy when risk is shared with forward-looking control variables

Note: Vertical axes refer to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axes refer to the horizon of the IRFs (in years). Solid lines denote point estimates and shaded areas denote 90% confidence bands. Red (blue) lines depict the estimates for the upper (lower) quartiles of $\beta_{S,h}$, $\beta_{K,h}$, $\beta_{F,h}$ or $\beta_{C,h}$. The Driscoll and Kraay (1998) standard errors are bootstrapped using 1000 iterations.
E.5 Inclusion of lagged residuals

Figure 12: Impact of monetary policy when the lagged residuals are included

- (a) All channels
- (b) Factor market channel
- (c) Fiscal channel
- (d) Credit market channel

**Note:** Vertical axes refer to the impact of a 100 basis point rate hike on regional GDP (in %). Horizontal axes refer to the horizon of the IRFs (in years). Solid lines denote point estimates and shaded areas denote 90% confidence bands. Red (blue) lines depict the estimates for the upper (lower) quartiles of $\beta_{S,h}^c$, $\beta_{K,h}^c$, $\beta_{F,h}^c$, or $\beta_{C,h}^c$. The Driscoll and Kraay (1998) standard errors are bootstrapped using 1000 iterations.
